Data parallelism: GPU computing
CUDA: atomic operations, privatization, algorithms
Atomic operations

- The basics atomic operation in hardware is something like a read-modify-write operation performed by a single hardware instruction on a memory location address
  - Read the old value, calculate a new value, and write the new value to the location
  - The hardware ensures that no other threads can perform another read-modify-write operation on the same location until the current atomic operation is complete
    - Any other threads that attempt to perform an atomic operation on the same location will typically be held in a queue
  - All threads perform their atomic operations serially on the same location
Atomic Operations in CUDA

• Performed by calling functions that are translated into single instructions (a.k.a. intrinsic functions or intrinsics)

• Operation on one 32-bit or 64-bit word residing in global or shared memory.

• Atomic functions can only be used in device functions

• Atomic add, sub, inc, dec, min, max, exch (exchange), CAS (compare and swap), and, or, xor
Some examples

• Atomic Add

• int atomicAdd(int* address, int val);
  
  • reads the 32-bit word old from the location pointed to by address in global or shared memory, computes (old + val), and stores the result back to memory at the same address. The function returns old.

• Unsigned 32-bit integer atomic add

• unsigned int atomicAdd(unsigned int* address, unsigned int val);

• Unsigned 64-bit integer atomic add

• unsigned long long int atomicAdd(unsigned long long int* address, unsigned long long int val);

• Single-precision floating-point atomic add (capability > 2.0)

• float atomicAdd(float* address, float val);

• Double precision floating-point atomic add (capability > 6.0)

• double atomicAdd(double* address, double val);
atomicCAS

• int atomicCAS(int* address, int compare, int val);

• unsigned int atomicCAS(unsigned int* address, unsigned int compare, unsigned int val);

• unsigned long long int atomicCAS(unsigned long long int* address, unsigned long long int compare, unsigned long long int val);

• reads the 32-bit or 64-bit word old located at the address address in global or shared memory, computes (old == compare ? val : old), and stores the result back to memory at the same address. These three operations are performed in one atomic transaction. The function returns old (Compare And Swap).
atomicCAS

• int atomicCAS(int* address, int compare, int val);

• unsigned int atomicCAS(unsigned int* address,
    unsigned int compare,
    unsigned int val);

• unsigned long long int atomicCAS(unsigned long long
    int* address,
    unsigned long long int
    compare,
    unsigned long long int
    val);

• reads the 32-bit or 64-bit word old located at the address address in global or shared memory, computes (old == compare ? val : old), and stores the result back to memory at the same address. These three operations are performed in one atomic transaction. The function returns old (Compare And Swap).

More precisely: *address=(*address==compare) ? val : *address;
atomicCAS

• Note that any atomic operation can be implemented based on `atomicCAS()` (Compare And Swap). For example, `atomicAdd()` for double-precision floating-point numbers is not available on devices with compute capability lower than 6.0 but it can be implemented as follows:

```c
#if __CUDA_ARCH__ < 600
__device__ double atomicAdd(double* address, double val)
{
    unsigned long long int* address_as_ull = (unsigned long long int*) address;
    unsigned long long int old = *address_as_ull;
    unsigned long long int assumed;
    do {
        assumed = old;
        old = atomicCAS(address_as_ull, assumed,
                        __double_as_longlong(val + __longlong_as_double(assumed)));
        // Note: uses integer comparison to avoid hang in case
        // of NaN (since NaN != NaN)
    } while (assumed != old);
    return __longlong_as_double(old);
}
#endif
```
atomicCAS

• Note that any atomic operation can be implemented based on atomicCAS() (Compare And Swap). For example, atomicAdd() for double-precision floating-point numbers is not available on devices with compute capability lower than 6.0 but it can be implemented as follows:

```c
#if __CUDA_ARCH__ < 600
__device__ double atomicAdd(double* address, double val)
{
    unsigned long long int* address_as_ull = (unsigned long long int*) address;
    unsigned long long int old = *address_as_ull;
    unsigned long long int assumed;
    do {
        assumed = old;
        old = atomicCAS(address_as_ull, assumed, __double_as_longlong(val + __longlong_as_double(assumed)));
        // Note: uses integer comparison to avoid hang in case
        //       of NaN (since NaN != NaN)
    } while (assumed != old);
    return __longlong_as_double(old);
}
#endif
```

Reinterpret the bits in the 64-bit signed integer value as a double-precision floating point value.
Critical section

- Using atomic instructions, in particular CAS, it is possible to implement a critical section. We need to use also `atomicExch()` that exchanges a value:

```c
__device__ int lock = 0;

__global__ void kernel() {
    // ...
    if (threadIdx.x==0) {
        // set lock
        do {} while(atomicCAS(&lock, 0, 1); // spin...
        // critical code section
        atomicExch(&lock, 0); // release lock
    }
}
```

We use thread 0 of each block for mutual exclusion
Memory fence

• atomicCAS can not pick stale values of the lock, since global atomics bypass L1 and are resolved in L2 cache, which is a device-wide resource

• But no one assures us that a programmer does not read the mutex variable (after all it is just a global variable…)

• To avoid reading stale values in other threads we need to force to read actual values, ie.. using a memory fence. GPUs implement a weak memory ordering…

• Use __threadfence()
__threadfence()
Lock structure

struct Lock {
    int *mutex;
    Lock( void ) {
        cudaMalloc( (void**)&mutex, sizeof(int) );
        cudaMemset( mutex, 0, sizeof(int) );
    }

    ~Lock( void ) {
        cudaFree( mutex );
    }

    __device__ void lock( void ) {
        while( atomicCAS( mutex, 0, 1 ) != 0 ); // spin lock: cycle until it sees 0
        __threadfence();
    }

    __device__ void unlock( void ) {
        __threadfence();
        atomicExch( mutex, 0 );
    }
};
Lock and warps

• Threads within a warp negotiating for a lock can be quite challenging due to the GPU warp-based execution:

```c
__device__ int lock;

__global__ void Deadlock() {
    while (atomicCAS(&lock, 0, 1) != 0){}
    // critical section
    atomicExch(&lock, 0);
}
```
Lock and warps

Threads in a warp execute in lockstep. The threads in a warp entering the while loop must all acquire the lock before any can proceed beyond that while loop. Unfortunately this is impossible, and there is deadlock.

__device__ int lock;

__global__ void Deadlock() {
    while (atomicCAS(&lock, 0, 1) != 0) {} // critical section
    atomicExch(&lock, 0);
}
Lock and warps

- A way to avoid the previous problem:

```cpp
__device__ int lock = 0;

__global__ void kernel() {
    bool blocked = true;
    while(blocked) {  
        if (0 == atomicCAS(&lock, 0, 1)) {
            doCriticJob();
            atomicExch(&lock, 0);
            blocked = false;
        }
    }
}
```

Each thread that acquires the lock has a chance to release it. All the threads waiting to lock are inside the same while loop, one of them will get the lock and then exit the loop. Once all threads have acquired/released the lock, the code continues after the loop.
Note: Managing mutexes or critical sections, especially when the negotiation is amongst threads in the same warp is notoriously difficult and fragile. The general advice is to avoid it.

If you must use mutexes or critical sections, have a single thread in the threadblock negotiate for any thread that needs it, then control behavior within the threadblock using intra-threadblock synchronization mechanisms, such as `__syncthreads()`.

```c
__device__ int lock = 0;

__global__ void kernel() {
    bool blocked = true;
    while(blocked) {
        if (0 == atomicCAS(&lock, 0, 1)) {
            doCriticJob();
            atomicExch(&lock, 0);
            blocked = false;
        }
    }
}
```

Each thread that acquires the lock has a chance to release it. All the threads waiting to lock are inside the same while loop, one of them will get the lock and then exit the loop. Once all threads have acquired/released the lock, the code continues after the loop.
Atomic operations and caches

- Atomic operations serialize simultaneous updates to a location, thus to improve performance the serialization should be as fast as possible
  - changing locations in global memory is slow: e.g. with an access latency of 200 cycles and 1 GHz clock the throughput of atomics is $\frac{1}{400}$ (atomics/clock) * 1 G (clocks/secs) = 2.5M atomics/secs (vs. the Gflops of modern GPUs)

- Cache memories are the primary tool for reducing memory access latency (e.g. 10s of cycle vs. 100s of cycles).

- Recent GPUs allow atomic operation to be performed in the last level cache, which is shared among all SMs.
Privatization

• The latency for accessing memory can be dramatically reduced by placing data in the shared memory. Shared memory is private to each SM and has very short access latency (a few cycles); this directly translates into increase throughput of atomic operations.

• The problem is that due to the private nature of shared memory, the updates by threads in one thread block is no longer visible to threads in other blocks.
Privatization

• The idea of privatization is to replicate highly contended data structures into private copies so that each thread (or each subset of threads) can access a private copy. The benefit is that the private copies can be accessed with much less contention and often at much lower latency.

• These private copies can dramatically increase the throughput for updating the data structures. The downside is that the private copies need to be merged into the original data structure after the computation completes. One must carefully balance between the level of contention and the merging cost.
__global__ void histogram_kernel(const char *input, unsigned int *bins,
                                unsigned int num_elements,
                                unsigned int num_bins) {

    unsigned int tid = blockIdx.x * blockDim.x + threadIdx.x;
    // Privatized bins
    extern __shared__ unsigned int bins_s[];
    for (unsigned int binIdx = threadIdx.x; binIdx < num_bins;
         binIdx += blockDim.x) {
        bins_s[binIdx] = 0;
    }
    __syncthreads();

    // Histogram
    for (unsigned int i = tid; i < num_elements; i += blockDim.x * gridDim.x) {
        atomicAdd(&((unsigned int)input[i]), 1);
    }
    __syncthreads();

    // Commit to global memory
    for (unsigned int binIdx = threadIdx.x; binIdx < num_bins;
          binIdx += blockDim.x) {
        atomicAdd(&bins[binIdx], bins_s[binIdx]);
    }
}
Example: histogram computation

```c
__global__ void histogram_kernel(const char *input, unsigned int *bins,
                               unsigned int num_elements,
                               unsigned int num_bins) {

  unsigned int tid = blockIdx.x * blockDim.x + threadIdx.x;
  // Privatized bins
  extern __shared__ unsigned int bins_s[];
  for (unsigned int binIdx = threadIdx.x; binIdx < num_bins;
       binIdx += blockDim.x) {
    bins_s[binIdx] = 0;
  }
  __syncthreads();
  // Histogram
  for (unsigned int i = tid; i < num_elements; i += blockDim.x * gridDim.x) {
    atomicAdd(&(bins_s[(unsigned int)input[i]]), 1);
  }
  __syncthreads();
  // Commit to global memory
  for (unsigned int binIdx = threadIdx.x; binIdx < num_bins;
       binIdx += blockDim.x) {
    atomicAdd(&(bins[binIdx]), bins_s[binIdx]);
  }
}
```

Dynamically allocated shared memory. To allocate it dynamically invoke the kernel with:

```c
dim3 blockDim(256), gridDim(30);
histogram_kernel<<<gridDim, blockDim,
                  num_bins * sizeof(unsigned int)>>>(input, bins, num_elements, num_bins);
```
Improving memory access

• A simple parallel histogram algorithm partitions the input into sections

• Each section is given to a thread, that iterates through it

• This makes sense in CPU code, where we have few threads, each of which can efficiently use the cache lines when accessing memory

• This access is less convenient in GPUs
Sectioned Partitioning (Iteration #1)
Sectioned Partitioning (Iteration #2)
Input Partitioning Affects Memory Access Efficiency

- Sectioned partitioning results in poor memory access efficiency
  - Adjacent threads do not access adjacent memory locations
  - Accesses are not coalesced
  - DRAM bandwidth is poorly utilized

- Change to interleaved partitioning
  - All threads process a contiguous section of elements
  - They all move to the next section and repeat
  - The memory accesses are coalesced
Interleaved Partitioning of Input

- For coalescing and better memory access performance
Interleaved Partitioning (Iteration 2)
A stride algorithm

```c
__global__ void histo_kernel(unsigned char *buffer,
                              long size, unsigned int *histo)
{

    int i = threadIdx.x + blockIdx.x * blockDim.x;

    // stride is total number of threads
    int stride = blockDim.x * gridDim.x;

    // All threads handle blockDim.x * gridDim.x
    // consecutive elements
    while (i < size) {
        atomicAdd( &histo[buffer[i]], 1);
        i += stride;
    }
}
```
A stride algorithm

Calculates a stride value, which is the total number threads launched during kernel invocation (`blockDim.x*gridDim.x`). In the first iteration of the `while` loop, each thread index the input buffer using its global thread index: Thread 0 accesses element 0, Thread 1 accesses element 1, etc. Thus, all threads jointly process the first `blockDim.x*gridDim.x` elements of the input buffer.

```c
int i = threadIdx.x + blockIdx.x * blockDim.x;

// stride is total number of threads
int stride = blockDim.x * gridDim.x;

// All threads handle blockDim.x * gridDim.x
// consecutive elements
while (i < size) {
    atomicAdd( &(histo[buffer[i]]), 1);
    i += stride;
}
```
A stride algorithm

Calculates a stride value, which is the total number of threads launched during kernel invocation (blockDim.x*gridDim.x). In the first iteration of the while loop, each thread index the input buffer using its global thread index: Thread 0 accesses element 0, Thread 1 accesses element 1, etc. Thus, all threads jointly process the first blockDim.x*gridDim.x elements of the input buffer.

```
int i = threadIdx.x + blockIdx.x * blockDim.x;

// stride is total number of threads
int stride = blockDim.x * gridDim.x;

// All threads handle blockDim.x * gridDim.x
// consecutive elements
while (i < size) {
    atomicAdd( &(histo[buffer[i]]), 1);
    i += stride;
}
```

The while loop controls the iterations for each thread. When the index of a thread exceeds the valid range of the input buffer (i is greater than or equal to size), the thread has completed processing its partition and will exit the loop.
CUDA: parallel patterns - convolution
Convolution (stencil)

- An array operation where each output data element is a weighted sum of a collection of neighboring input elements.
- The weights used in the weighted sum calculation are defined by an input mask array, commonly referred to as the convolution kernel.
- We will refer to these mask arrays as convolution masks to avoid confusion.
- The value pattern of the mask array elements defines the type of filtering done.
Convolution (stencil)

• An array operation where each output data element is a weighted sum of a collection of neighboring input elements

• The weights used in the weighted sum calculation are defined by an input mask array, commonly referred to as the convolution kernel

• We will refer to these mask arrays as convolution masks to avoid confusion.

• Often performed as a filter that transforms signal or pixel values into more desirable values.
1D Convolution Example

• Commonly used for audio processing

• Mask size is usually an odd number of elements for symmetry (5 in this example)

• The figure shows calculation of $P[2]$

Example: calculation of $P[3]$
Convolution Boundary Condition

- Calculation of output elements near the boundaries (beginning and end) of the array need to deal with “ghost” elements

- Different policies (0, replicates of boundary values, use of symmetrical values, etc.)
A 1D Convolution Kernel with Boundary Condition Handling

```c
__global__ void convolution_1D_basic_kernel(float *N, float *M, float *P, int Mask_Width, int Width) {
    int i = blockIdx.x*blockDim.x + threadIdx.x;
    float Pvalue = 0;
    int N_start_point = i – (Mask_Width/2);

    for (int j = 0; j < Mask_Width; j++) {
        if (N_start_point + j >= 0 &&
            N_start_point + j < Width) {
            Pvalue += N[N_start_point + j]*M[j];
        }
    }

    P[i] = Pvalue;
}
```

- This kernel forces all elements outside the valid input range to 0
A 1D Convolution Kernel with Boundary Condition Handling

```c
__global__ void convolution_1D_basic_kernel(float *N, float *M, float *P, int Mask_Width, int Width) {
    int i = blockIdx.x*blockDim.x + threadIdx.x;
    float Pvalue = 0;  // Use a register
    int N_start_point = i - (Mask_Width/2);

    for (int j = 0; j < Mask_Width; j++) {
        if (N_start_point + j >= 0 &&
            N_start_point + j < Width) {
            Pvalue += N[N_start_point + j]*M[j];
        }
    }

    P[i] = Pvalue;
}
```

- This kernel forces all elements outside the valid input range to 0
A 1D Convolution Kernel with Boundary Condition Handling

```c
__global__ void convolution_1D_basic_kernel(float *N, float *M, float *P, int Mask_Width, int Width) {
    int i = blockIdx.x*blockDim.x + threadIdx.x;

    float Pvalue = 0; // Use a register
    int N_start_point = i - (Mask_Width/2);

    for (int j = 0; j < Mask_Width; j++) {
        if (N_start_point + j >= 0 &&
            N_start_point + j < Width) {
            Pvalue += N[N_start_point + j]*M[j];
        }
    }

    P[i] = Pvalue;
}
```

- This kernel forces all elements outside the valid input range to 0

    }
}
Improving convolution kernel

• Use tiling for the N array element

• Use constant memory for the M mask
  • it’s typically small and is not changed
  • can be read by all threads of the grid

#define MAX_MASK_WIDTH 10
__constant__ float M[MAX_MASK_WIDTH];
cudaMemcpyToSymbol(M, M_h, Mask_Width*sizeof(float));
Improving convolution kernel

• Use tiling for the N array element

• Use constant memory for the M mask
  • it’s typically small and is not changed
  • can be read by all threads of the grid

```c
#define MAX_MASK_WIDTH 10
__constant__ float M[MAX_MASK_WIDTH];

cudaMemcpyToSymbol(M, M_h, Mask_Width*sizeof(float));
```
__global__ void convolution_1D_basic_kernel(float *N, float *P,
    int Mask_Width, int Width) {

    int i = blockIdx.x*blockDim.x + threadIdx.x;
    float Pvalue = 0;
    int N_start_point = i - (Mask_Width/2);
    for (int j = 0; j < Mask_Width; j++) {
        if (N_start_point + j >= 0 && N_start_point + j < Width) {
            Pvalue += N[N_start_point + j]*M[j];
        }
    }
    P[i] = Pvalue;
}
Convolution with constant memory

```c
__global__ void convolution_1D_basic_kernel(float *N, float *P,
                                           int Mask_Width, int Width) {

    int i = blockIdx.x*blockDim.x + threadIdx.x;
    float Pvalue = 0;
    int N_start_point = i - (Mask_Width/2);
    for (int j = 0; j < Mask_Width; j++) {
        if (N_start_point + j >= 0 && N_start_point + j < Width) {
            Pvalue += N[N_start_point + j]*M[j];
        }
    }
    P[i] = Pvalue;
}
```

2 floating-point operations per global memory access \((N)\)
CUDA: parallel patterns - convolution & tiling
Tiling & convolution

- Calculation of adjacent output elements involve shared input elements
  - We can load all the input elements required by all threads in a block into the shared memory to reduce global memory accesses
Input Data Needs

- Assume that we want to have each block to calculate T output elements
  - T + Mask_Width -1 input elements are needed to calculate T output elements
  - T + Mask_Width -1 is usually not a multiple of T, except for small T values
  - T is usually significantly larger than Mask_Width
Definition – output tile

- Each thread block calculates an output tile
- Each output tile width is O_TILE_WIDTH
- For each thread:
  - O_TILE_WIDTH is 4 in this example
Definition - Input Tiles

- Each input tile has all values needed to calculate the corresponding output tile.
Two Design Options

- Design 1: The size of each thread block matches the size of an output tile
  - All threads participate in calculating output elements
  - blockDim.x would be 4 in our example
  - Some threads need to load more than one input element into the shared memory
- Design 2: The size of each thread block matches the size of an input tile
  - Some threads will not participate in calculating output elements
  - blockDim.x would be 8 in our example
  - Each thread loads one input element into the shared memory
Thread to Input and Output Data Mapping

- For each thread:
  - \( \text{index}_i = \text{index}_o - n \)
  - where \( n \) is \( \text{Mask Width} / 2 \)
  - \( n \) is 2 in this example
Loading input tiles

All threads participate:

```c
float output = 0.0f;

if((index_i >= 0) && (index_i < Width)) {
    Ns[tx] = N[index_i];
} else {
    Ns[tx] = 0.0f;
}
```
Calculating output

- Some threads do not participate: Only Threads 0 through \( 0 \_ \text{TILE}\_\text{WIDTH}-1 \) participate in calculation of output.

\[
\text{index}_o = \text{blockIdx}.x*\text{O}\_\text{TILE}\_\text{WIDTH} + \text{threadIdx}.x
\]

\[
\text{if (threadIdx}.x < \text{O}\_\text{TILE}\_\text{WIDTH})\{
\]

\[
\text{output} = 0.0f;
\]

\[
\text{for}(j = 0; j < \text{Mask}\_\text{Width}; j++) \{ \\
\text{output} += \text{M}[j] \times \text{Ns}[j+\text{threadIdx}.x]; \\
\}
\]

\[
\text{P[\text{index}_o]} = \text{output};
\]

\}
Setting Block Size

```c
#define O_TILE_WIDTH 1020
#define BLOCK_WIDTH (O_TILE_WIDTH + 4)

dim3 dimBlock(BLOCK_WIDTH, 1, 1);
dim3 dimGrid((Width-1)/O_TILE_WIDTH+1, 1, 1)
```

- The Mask_Width is 5 in this example
- In general, block width should be
  - output tile width + (mask width-1)
Shared Memory Data Reuse

\[
\begin{bmatrix}
2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\
\end{bmatrix}
\]

\( N_{ds} \)

Mask_Width is 5

Element 2 is used by thread 4 (1X)
Element 3 is used by threads 4, 5 (2X)
Element 4 is used by threads 4, 5, 6 (3X)
Element 5 is used by threads 4, 5, 6, 7 (4X)
Element 6 is used by threads 4, 5, 6, 7 (4X)
Element 7 is used by threads 5, 6, 7 (3X)
Element 8 is used by threads 6, 7 (2X)
Element 9 is used by thread 7 (1X)
Ghost/Halo cells
Evaluating tiling
An 8-element Convolution Tile

- For Mask_Width=5, we load 8+5-1=12 elements (12 memory loads)
Evaluating reuse

• Each output P element uses 5 N elements:

\[P[8] \text{ uses } N[6], N[7], N[8], N[9], N[10]\]
\[P[9] \text{ uses } N[7], N[8], N[9], N[10], N[11]\]
\[P[10] \text{ use } N[8], N[9], N[10], N[11], N[12]\]

...  
\[P[14] \text{ uses } N[12], N[13], N[14], N[15], N[16]\]
\[P[15] \text{ uses } N[13], N[14], N[15], N[16], N[17]\]
Evaluating reuse

- Each output P element uses 5 N elements:

  P[8] uses N[6], N[7], N[8], N[9], N[10]

  \((8+5-1)=12\) elements loaded

  8*5 global memory accesses replaced by shared memory accesses
  This gives a bandwidth reduction of \(\frac{40}{12}=3.3\)
General 1D tiled convolution

- \( O_{\text{TILE WIDTH}} + \text{MASK_WIDTH} - 1 \) elements loaded for each input tile

- \( O_{\text{TILE WIDTH}} \times \text{MASK_WIDTH} \) global memory accesses replaced by shared memory accesses

- This gives a reduction factor of

\[
\frac{O_{\text{TILE WIDTH}} \times \text{MASK_WIDTH}}{O_{\text{TILE WIDTH}} + \text{MASK_WIDTH} - 1}
\]

- This ignores ghost elements in edge tiles.
Another Way to Look at Reuse

N[6] is used by P[8] (1X)
N[7] is used by P[8], P[9] (2X)
N[8] is used by P[8], P[9], P[10] (3X)
N[9] is used by P[8], P[9], P[10], P[11] (4X)
N[10] is used by P[8], P[9], P[10], P[11], P[12] (5X)
... (5X)
N[14] is used by P[12], P[13], P[14], P[15] (4X)
N[15] is used by P[13], P[14], P[15] (3X)
Another Way to Look at Reuse

- The total number of global memory accesses to the \((8+5-1)=12\) elements of \(N\) that is replaced by shared memory accesses is:

\[
1+2+3+4+5*(8-5+1)+4+3+2+1 = 10+20+10 = 40
\]

- So the reduction is \(40/12 = 3.3\)
General 1D tiling

• The total number of global memory accesses to the input tile can be calculated as

\[1 + 2 + \ldots + \text{MASK_WIDTH}-1 + \text{MASK_WIDTH} \times (\text{O TILE WIDTH} - \text{MASK_WIDTH} + 1) + \text{MASK_WIDTH}-1 + \ldots + 2 + 1\]

\[= \text{MASK_WIDTH} \times (\text{MASK_WIDTH}-1) + \text{MASK_WIDTH} \times (\text{O TILE WIDTH} - \text{MASK_WIDTH} + 1)\]

\[= \text{MASK_WIDTH} \times \text{O TILE WIDTH}\]

• For a total of \text{O TILE WIDTH} + \text{MASK_WIDTH} - 1 input tile elements
Examples of Bandwidth Reduction for 1D

- The reduction ratio is:

- \( \text{MASK_WIDTH} \times \text{O_TILE_WIDTH} / (\text{O_TILE_WIDTH} + \text{MASK_WIDTH} - 1) \)

<table>
<thead>
<tr>
<th>O_TILE_WIDTH</th>
<th>16</th>
<th>32</th>
<th>64</th>
<th>128</th>
<th>256</th>
</tr>
</thead>
<tbody>
<tr>
<td>MASK_WIDTH = 5</td>
<td>4.0</td>
<td>4.4</td>
<td>4.7</td>
<td>4.9</td>
<td>4.9</td>
</tr>
<tr>
<td>MASK_WIDTH = 9</td>
<td>6.0</td>
<td>7.2</td>
<td>8.0</td>
<td>8.5</td>
<td>8.7</td>
</tr>
</tbody>
</table>
2D convolution tiles

- \((O\_TILE\_WIDTH+MASK\_WIDTH-1)^2\) input elements need to be loaded into shared memory

- The calculation of each output element needs to access \(MASK\_WIDTH^2\) input elements

- \(O\_TILE\_WIDTH^2 \times MASK\_WIDTH^2\) global memory accesses are converted into shared memory accesses

- The reduction ratio is

  - \(O\_TILE\_WIDTH^2 \times MASK\_WIDTH^2 / (O\_TILE\_WIDTH+MASK\_WIDTH-1)^2\)
Bandwidth Reduction for 2D

- The reduction ratio is:

\[
\frac{O\_TILE\_WIDTH^2 \times MASK\_WIDTH^2}{(O\_TILE\_WIDTH + MASK\_WIDTH - 1)^2}
\]

- Tile size has significant effect on the memory bandwidth reduction ratio.
- This often argues for larger shared memory size.
CUDA: parallel patterns - map/gather/scatter
Map

• Takes an input list $i$

• Applies a function $f$

• Writes the results in a list $o$, by applying $f$ to all the members of $i$

• A CUDA kernel where $i$ and $o$ are memory locations determined by threadIdx... implements this pattern
Gather

• Multiple inputs and single coalesced output

• Might have sequential loading or random access

  • Affect memory performance, e.g. if thread 1 gets input 0 and 1, thread 2 gets input 2 and 3, and so on... we have coalesced memory access. With random access no.

• Differs from map due to multiple inputs
Scatter

• Reads from a single input and writes to one or many

• Can be implemented in CUDA using atomics

• Write pattern will determine performance
  • e.g. do we have write collisions? Random access write?
CUDA: parallel patterns - reduction
Reduction

- A reduction is where all elements of a set have a common binary associative operator ($\oplus$) applied to them to “reduce” the set to a single value
  - Binary associative = order in which operations is performed on set does not matter
    - Most obvious example is addition (Summation)
    - Other examples, Maximum, Minimum, product
Tree based

- At each step data is reduced by a factor of 2

- In CUDA there is no global synchronisation so we need to split the execution into multiple stages
N-1 operations in $\log_2(N)$ steps
Avg. parallelism: $(N-1)/\log_2(N)$
For $N=1000000$ avg. parallelism is 50000, but peak resource req. is 500000

• At each step data is reduced by a factor of 2

• In CUDA there is no global synchronisation so we need to split the execution into multiple stages
Parallel sum reduction

- Parallel implementation
  - Each thread adds two values in each step
  - Recursively halve # of threads
  - Takes $\log(n)$ steps for $n$ elements, requires $n/2$ threads

- Assume an in-place reduction using shared memory
  - The original vector is in device global memory
  - The shared memory is used to hold a partial sum vector
  - Initially, the partial sum vector is simply the original vector
  - Each step brings the partial sum vector closer to the sum
  - The final sum will be in element 0 of the partial sum vector

- Reduces global memory traffic due to reading and writing partial sum values
- Thread block size limits $n$ to be less than or equal to 2,048
A Parallel Sum Reduction Example

- Naïve thread-to-data mapping
  - Each thread is responsible for an even-index location of the partial sum vector (location of responsibility)
  - After each step, half of the threads are no longer needed
  - One of the inputs is always from the location of responsibility
  - In each step, one of the inputs comes from an increasing distance away

- Step 1 - Stride 1
- Step 2 - Stride 2
- Step 3 - Stride 4
A Simple Thread Block Design

- Each thread block takes 2*BlockDim.x input elements
- Each thread loads 2 elements into shared memory

```c
__shared__ float partialSum[2*BLOCK_SIZE];

unsigned int t = threadIdx.x;
unsigned int start = 2*blockIdx.x*blockDim.x;
partialSum[t] = input[start + t];
partialSum[blockDim+t] = input[start + blockDim.x +t];
```
Reduction steps

for (unsigned int stride = 1; stride <= blockDim.x; stride *= 2) {
    __syncthreads();
    if (t % stride == 0)
        partialSum[2*t] += partialSum[2*t+stride];
}

• __syncthreads() is needed to ensure that all elements of each version of partial sums have been generated before we proceed to the next step
Reduction steps

```c
for (unsigned int stride = 1; stride <= blockDim.x; stride *= 2) {
    __syncthreads();
    if (t % stride == 0)
        partialSum[2*t] += partialSum[2*t+stride];
}
```

- At the end of the kernel, Thread 0 in each block writes the sum of the thread block in `partialSum[0]` into a vector indexed by the `blockIdx.x`
- There can be a large number of such sums if the original vector is very large
  - The host code may iterate and launch another kernel
- If there are only a small number of sums, the host can simply transfer the data back and add them together
- Alternatively, Thread 0 of each block could use atomic operations to accumulate into a global sum variable.
Reduction steps

```c
for (unsigned int stride = 1; stride <= blockDim.x; stride *= 2) {
    __syncthreads();
    if (t % stride == 0)
        partialSum[2*t] += partialSum[2*t+stride];
}
```

- At the end of the kernel, Thread 0 in each block writes the sum of the thread block in `partialSum[0]` into a vector indexed by the `blockIdx.x`
- There can be a large number of such sums if the original vector is very large
  - The host code may iterate and launch another kernel
- If there are only a small number of sums, the host can simply transfer the data back and add them together
- Alternatively, Thread 0 of each block could use atomic operations to accumulate into a global sum variable.

```c
if (t==0) output[blockIdx.x]=partialSum[0];
```
Reduction steps

for (unsigned int stride = 1; stride <= blockDim.x; stride *= 2) {
    __syncthreads();
    if (t % stride == 0)
        partialSum[2*t] += partialSum[2*t+stride];
}

if (t==0) output[blockIdx.x]=partialSum[0];

Problem: highly divergent branching: very poor performance

- At the end of the kernel, Thread 0 in each block writes the sum of the thread block in partialSum[0] into a vector indexed by the blockIdx.x
- There can be a large number of such sums if the original vector is very large
  - The host code may iterate and launch another kernel
- If there are only a small number of sums, the host can simply transfer the data back and add them together
- Alternatively, Thread 0 of each block could use atomic operations to accumulate into a global sum variable.
Problems

- In each iteration, two control flow paths will be sequentially traversed for each warp
  - Threads that perform addition and threads that do not
  - Threads that do not perform addition still consume execution resources
- Half or fewer of threads will be executing after the first step
  - All odd-index threads are disabled after first step
- After the 5th step, entire warps in each block will fail the if test, poor resource utilization but no divergence
  - This can go on for a while, up to 6 more steps (stride = 32, 64, 128, 256, 512, 1024), where each active warp only has one productive thread until all warps in a block retire
Problems

• In each iteration, two control flow paths will be sequentially traversed for each warp.

  • Threads that perform addition and threads that do not.

  • Threads that do not perform addition still consume execution resources.

• Half or fewer of threads will be executing after the first step.

  • All odd-index threads are disabled after first step.

  • After the 5th step, entire warps in each block will fail the if test, poor resource utilization but no divergence.

• This can go on for a while, up to 6 more steps (stride = 32, 64, 128, 256, 512, 1024), where each active warp only has one productive thread until all warps in a block retire.

Solutions:

• Change index usage to improve divergence behavior.

• Compact partial sums into front locations of partialSum[] array.

• Keep the active threads consecutive.
Problems

• In each iteration, two control flow paths will be sequentially traversed for each warp.
• Threads that perform addition and threads that do not.
• Threads that do not perform addition still consume execution resources.
• Half or fewer of threads will be executing after the first step.
• All odd-index threads are disabled after first step.
• After the 5th step, entire warps in each block will fail the if test, poor resource utilization but no divergence.
• This can go on for a while, up to 6 more steps (stride = 32, 64, 128, 256, 512, 1024), where each active warp only has one productive thread until all warps in a block retire.

Solutions:

• Keep the active threads consecutive.

Thread 0  Thread 1  Thread 2  Thread 3
Step 1 - Stride 4  Step 2 - Stride 2  Step 3 - Stride 1
Better reduction kernel

for (unsigned int stride = blockDim.x; stride > 0; stride /= 2) {
    __syncthreads();
    if (t < stride)
        partialSum[t] += partialSum[t+stride];
}

- For a 1024 thread block
  - No divergence in the first 5 steps
    - 1024, 512, 256, 128, 64, 32 consecutive threads are active in each step
    - All threads in each warp either all active or all inactive
    - The final 5 steps will still have divergence
Better reduction kernel

```c
for (unsigned int stride = blockDim.x; stride > 0; stride /= 2)
{
    __syncthreads();
    if (t < stride)
        partialSum[t] += partialSum[t+stride];
}
```

- For a 1024 thread block
  - No divergence in the first 5 steps
    - 1024, 512, 256, 128, 64, 32 consecutive threads are active in each step
    - All threads in each warp either all active or all inactive
  - The final 5 steps will still have divergence

Further improvements:
- Loop unrolling
- Increasing parallelism
- Perform an initial add during data load
CUDA: parallel patterns - scan
Scan (prefix sum)

• Scan: computes all partial reduction of a collection

• For every output in a collection, a reduction of the input up to that point is computed

• If the function being used is associative, the scan can be parallelized

• Parallelizing a scan is not obvious at first, because of dependencies to previous iterations in the serial loop

• A parallel scan will require more operations than a serial version
Scan (prefix sum)

• Scan: computes all partial reduction of a collection

• For every output in a collection, a reduction of the input up to that point is computed

• If the function being used is associative, the scan can be parallelized

More formally:

The scan operation takes a binary associative operator $\oplus$, and an array of $n$ elements $[x_0, x_1, \ldots, x_{n-1}]$, and returns the array $[x_0, (x_0 \oplus x_1), \ldots, (x_0 \oplus x_1 \oplus \ldots \oplus x_{n-1})]$. 
Scan

Serial scan

Parallel scan
Scan

- Frequently used for parallel work assignment and resource allocation
- A key primitive in many parallel algorithms to convert serial computation into parallel computation
- A foundational parallel computation pattern, useful for many algorithms like:
  - Radix sort
  - Quicksort
  - String comparison
  - Lexical analysis
  - Stream compaction
  - Polynomial evaluation
  - Solving recurrences
  - Tree operations
  - Histograms, ….
Naïve solutions

- A serial version:
  \[ y[0] = x[0]; \]
  \[ \text{for } (i = 1; i < \text{Max}_i; i++) \]
  \[ y[i] = y[i-1] + x[i]; \]

- is computationally efficient: N additions needed for N elements - O(N)!

- A parallel version may assign a thread to each element:
  \[ y0 = x0 \]
  \[ y1 = x0 + x1 \]
  \[ y2 = x0 + x1 + x2 \]
  \[ y3 = x0 + x1 + x2 + x3 \]

- is not efficient!
A Better Parallel Scan Algorithm

1. Read input from device global memory to shared memory

2. Iterate log(n) times; stride from 1 to n-1: double stride each iteration

3. Write output from shared memory to device memory

- Active threads stride to n-1 (n-stride threads)
- Thread j adds elements j and j-stride from shared memory and writes result into element j in shared memory
- Requires barrier synchronization, once before read and once before write
A Better Parallel Scan Algorithm

1. Read input from device global memory to shared memory

2. Iterate log(n) times; stride from 1 to n-1: double stride each iteration

3. Write output from shared memory to device memory

```
XY 3 1 7 0 4 1 6 3
STRIDE 1
XY 3 4 8 7 4 5 7 9
STRIDE 2
XY 3 4 11 11 12 12 11 14
```

ITERATION = 2
STRIDE = 2
A Better Parallel Scan Algorithm

1. Read input from device global memory to shared memory
2. Iterate log(n) times; stride from 1 to n-1: double stride each iteration
3. Write output from shared memory to device memory
Handling Dependencies

- During every iteration, each thread can overwrite the input of another thread

  - Barrier synchronization to ensure all inputs have been properly generated (i.e. __syncthreads())

  - All threads secure input operand that can be overwritten by another thread

    - Barrier synchronization is required to ensure that all threads have secured their inputs

  - All threads perform addition and write output
__global__ void work_inefficient_scan_kernel(float *X, float *Y, int InputSize) {
    __shared__ float XY[SECTION_SIZE];

    int i = blockIdx.x * blockDim.x + threadIdx.x;
    if (i < InputSize) {
        XY[threadIdx.x] = X[i];
    }

    // the code below performs iterative scan on XY
    for (unsigned int stride = 1; stride < blockDim.x; stride *= 2) {
        __syncthreads();
        if(threadIdx.x >= stride)
            XY[threadIdx.x] += XY[threadIdx.x - stride];
    }

    __syncthreads();
    if (i < InputSize) {
        Y[i] = XY[threadIdx.x];
    }
}

• This Scan executes log$_2$(n) parallel iterations with n=SECTION_SIZE
  • The iterations do (n-1), (n-2), (n-4),...,(n- n/2) adds each
  • Total adds: n * log$_2$(n) - (n-1) \rightarrow O(n*log$_2$(n)) work

• This scan algorithm is not work efficient
  • Sequential scan algorithm does n adds
  • A factor of log$_2$(n) can hurt: 10x for 1024 elements!

A parallel algorithm can be slower than a sequential one when execution resources are saturated from low work efficiency
Improving efficiency

• Balanced Trees
  • Form a balanced binary tree on the input data and sweep it to and from the root
  • Tree is not an actual data structure, but a concept to determine what each thread does at each step

• For scan:
  • Traverse down from leaves to the root building partial sums at internal nodes in the tree
    • The root holds the sum of all leaves
  • Traverse back up the tree building the output from the partial sums
Parallel Scan - Reduction Phase

// $XY[2*\text{BLOCK\_SIZE}]$ is in shared memory

for (unsigned int stride = 1; stride <= \text{BLOCK\_SIZE};
    stride *= 2) {
    __syncthreads();
    int index = (threadIdx.x + 1) * stride * 2 - 1;
    if (index < 2*\text{BLOCK\_SIZE})
        $XY[index] += XY[index-stride]$;
}

- $\text{threadIdx.x} + 1 = 1, 2, 3, 4, \ldots$
- $\text{stride} = 1$,
- $\text{index} = 1, 3, 5, 7, \ldots$
Parallel Scan - Post Reduction Reverse Phase

Move (add) a critical value to a central location where it is needed
Parallel Scan - Post Reduction Reverse Phase
Parallel Scan - Post Reduction Reverse Phase

Putting together
Post Reduction Reverse Phase Kernel Code

```c
for (unsigned int stride = BLOCK_SIZE/2; stride > 0; stride /= 2) {
    __syncthreads();
    int index = (threadIdx.x+1) * stride * 2 - 1;
    if(index+stride < 2*BLOCK_SIZE) {
        XY[index + stride] += XY[index];
    }
}

__syncthreads();
if (i < InputSize)
    Y[i] = XY[threadIdx.x];
```

- First iteration for 16-element section
- threadIdx.x = 0
- stride = BLOCK_SIZE/2 = 8/2 = 4
- index = 8-1 = 7
